Instructions:

- 1. This is a 2-hr exam. Closed book and notes
- 2. If a description to an algorithm or a proof is required please limit your description or proof to within 150 words, preferably not exceeding the space allotted for that question.
- 3. No space other than the pages in the exam booklet will be scanned for grading.
- 4. If you require an additional page for a question, you can use the extra page provided within this booklet. However please indicate clearly that you are continuing the solution on the additional page.

Q1 Score: 12.0 / 20.0 (omple to

1) 20 pts

Mark the following statements as **TRUE** or **FALSE**. No need to provide any justification.

[TRUE/FALSE] FOLK

The depths of any two leaves in a binomial heap differ by at most 1.

I TKUE/FALSE

Given that all edges in a graph G are of equal weight, then the shortest path between any two vertices in G can be computed in linear time. False

[TRUE/FALSE]

Given a connected graph G with at least two edges having the same cost, there will be at least two distinct minimum spanning trees in G.

TRUE/FALSE

Provided the BFS and DFS trees of a connected undirected graph with the same initial vertex, the distance between two vertices in the DFS tree cannot be smaller than distance in the BFS tree.

[TP/E/FALSE].

In a graph, if one raises the lengths of all edges to the power 3, the minimum spanning tree will stay the same. $T_{Y}(M)$

[TRUE/FALSE]

In Huffman coding, the item with the second-lowest probability is always at the leaf that is furthest from the root.

[TRUE/FALSE]

The shortest path between two nodes in a graph could change if the weight of each edge is increased by an identical positive number.

[TRIE/FALSE]

The shortest path in a weighted DAG can be found in linear time. Full

[TRUE/FAZSE]

If an operation takes O(1) amortized time, then that operation takes $\underline{O(1)}$ worst case time.

[TRUE/FALSE]

In Mbonacci heaps, the decreaseKey operation takes O(1) worst case time.

In the following table, for each pair of expressions (f(n), g(n)), tell whether f(n) is $O(g(n)), \Theta(g(n)), \Omega(g(n))$ of these expressions. Put symbol O, Θ, Ω in the empty cells in the table. The first row, $f(n) = n^2$ is filled to help you understand this problem.

3) 12 pts
Run Dijkstra's algorithm on the following directed graph, to compute distances from node 1 to all the other nodes. List the vertices in the order they are added to the shortest path tree. You do not need to demonstrate all details of the algorithm

4) 12 pts
Suppose we define a new kind of directed graph in which positive weights are assigned to the vertices but not to the edges. If the length of a path is defined by the total weight of all nodes on the path, describe an algorithm that finds the shortest path between two given points A and B within this graph. Hint: modify a given graph.

Consider a graph on, with each node how. positive weights. In this graph, we need to find the shortest distance between two point A × B. The length of path is the rum of the vertice weights in the graph. Thus our minimum path will be at least the rum of weights of Now, let's construct another graph or such that the edge (U,V) carries weight of vertice u and edge. (V, w) carries weight of vertice V where (U,V) is edge from u to V and Wwi is edge from vtow Thus, now or is a weighted directed graph and we can non Dijkstra's algorithm on (1) to find shortest distance between A&B within this graph

5) 13 pts Consider a singly linked list data structure that stores a sequence of items in any order. To access the item in the *i*-th position requires time *i*. Also, any two contiguous items can be swapped in constant time. The goal is to allow access to a sequence of *n* items in a minimal amount of time. The TRANSPOSE is a heuristic that improves accessing time if the same is accessed again. TRANSPOSE works in the following way: after accessing x, if x is not at the front of the list, wap it with its next neighbor toward the front. Prove that the amortized cost of a single access is at least linear, i.e. Ω(n).

etem at e, time = i swapping = constant We need to prove that amortized cas Access Time Positionof nrgle occan is Il: n which is at pontion i. and connoler that in best case, n is Consider accord again and again then the time taken by the pirit accent of cox and for precarive accept to u, time taken will be constant. Thus, can conclude that the amortzed a nigle accen is at least linear ie ie the best case for accessing n items is at securt unear.

Start cluster has constant distance between their and each cluster has a constant distance between their between each other given by some abstract representation.

Suppose you have n objects with defined distances d(u,v) between each pair of them. d(u, v) may be an actual distance, or some abstract representation of how dissimilar two objects are. Your task is to group these objects in such a way that objects within a single group have small distances between them, and objects across groups have larger distances between them. This problem is called *clustering*. Propose an algorithm to separate given n objects into $k \le n$ clusters (groups), so that the

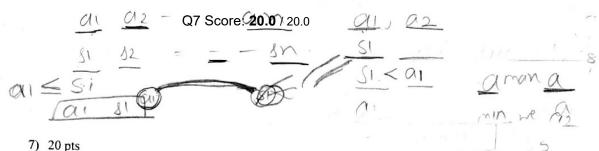

we have distances d(u,v) between each
peux of eterns. For a graph or with

Var, and MST for this graph, graph

The MST will connect the items with smaller distance between them and thus group them all together forming a cluster. And, thus there will be $K \leq n$ clusters. These clusters will be connected to each other in such a way that the clusters of items are least different from each other. The distance of our about is to marriage distance

Please see back side of this page for enplanation

each cluster-

Suppose there are n children at the birthday party, and the birthday cake is sliced into n slices with sizes $s_1, s_2, ..., s_n$ (where s_k is the weight of slice k) The cake was not perfectly sliced, so no slice has the same weight as others. Given the appetite of each child $a_1, a_2, ..., a_n$ (where a_k is a measure of child k's appetite in terms of cake weight), we want to distribute the slices (one slice per child) to fulfill every child's appetite. We say, a child's appetite is fulfilled if his/her slice weighs greater than or equal to his/her appetite.

a) Describe an algorithm to determine whether it is possible for such a distribution of the slices. (8 pts)

We maintain two min-heaps. A> One will have the weights of the cake Mices B>The other will have the appetite of the children Let the first min heap be A, and recond neop be B We take the minimum of both heaps and compa of min(B) < min(A), we form a pair and remove the min element from AX B both. If min(B) > min(A), we gremove the min(A) clemen and repeat the above steps. The total number of pairs will give the number of satisfied. The remaining children will not have children whose appetite is b) Determine the runtime complexity of your algorithm. (4 pts) their apetite satisfied heaps, et takes ocn time. To find and delete min dements, at takes Occupy) and we do this for n times in worst care - total = o(n+nlogn)

1 @ 2 3 5 1 9 11 12 child with at 12 3 5 wh 10 < a

c) Prove the correctness of your algorithm.(8 pts)

In our algorithm, we shook a still with minimum appetite and try to mate it with the cake of minimum weight. If the cake did of minimum weight cannot satisfy the appetite of white having lower appetite, then that slike of cake cannot satisfy the appetite of any other child is because the appetites are in minimum help and the next children will have appeared one than the previous one. Hence our algorithm is correct.
